OpenMP Outline

NUMA Outline

- The problem: "Where? Who? What?"
- Touch-first and touch-by-all policy
- Threads affinity

Where do the threads run?

As we have seen when we discussed the modern architectures, a unique central memory with a fixed bandwidth would be a major bottleneck in a system with a fast growing number of cores/sockets and sockets.

The problem is avoided by physically disjointing the memory in separated units (the *memory banks*) each of which is connected to a socket; All the sockets are inter-connected so that each core can access all the memory and a cachecoherency system "glues" the data.

This way, the resulting aggregated bandwidth scales as the number of sockets (although, we know, the cache-coherency becomes the new limiting factor).

However, the major drawback is that the access time is no more uniform. This has severe consequences on how you have to write and run your codes.

Where do the threads run?

OpenMP and the OS offer the capability to decide where each thread have to run, i.e. on which core and/or how the threads have to distribute on the available cores.

We know that each core may have the capability of running more than one thread, which is called (*) Simultaneous MultiThreading (SMT). In the next slides, let's call **strands** or **hwthreads** (hardware threads) the different threads that a physical core could run, as opposed to "swthreads" (software threads) that indicates the OpenMP threads.

The placement of OpenMP threads on cores is called "threads affinity".

Threads affinity

The *Threads affinity* is defined as the mapping of the threads on the underlying cores. The goal is to maximize the efficiency of the memory access on a strongly hierarchical memory system.

As usual, what "efficient" is depends on the details of each specific case.

For instance, if *n* threads work on shared data, it would be more efficient if they share the L2 cache – or in other words, they run on the same socket – so that frequently used data are at hands for all of them.

Conversely, if *n* threads work on independent memory segments, the most efficient choice is to maximize the memory bandwidth over the shortest core-to-ram path.

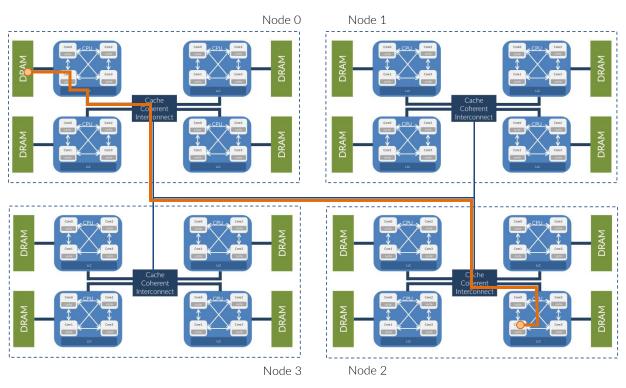

Where? Who? What?

The aim is to have as few remote memory accesses as possible. That depends on

- Where: i.e. in what memory bank the data are;
- Who: is accessing them, i.e. which thread → how are the threads distributed on the cores;
- What: how is the workload distributed among the threads;

NUMA rationale

In principle, you want to be able to distribute the work in an optimal way, i.e. without any resource (computational power, caches and memory) contention.

To do that, you must be able to place each OpenMP *swthread* to a dedicated computational resource, and to grant it the fastest possible access to "its own" data.

So, you need to:

- explicitly bind the threads to "cores", i.e. hwthreads
- explicitly allocate memory on the best suited physical memory
- minimize the remote memory access
- In case, to migrate memory and/or swthreads to one NUMA node to another, or to one hwthreads to another respectively

Threads affinity - RATIONALE

What is the "optimal" way to place the swthreads in a node depends on the nature of the algorithm and the data you are dealing with.

Having the swthreads "distant" from each other:

- may increase the aggregate bandwidth i.e. each hwthread could fully exploit its available bandwidth - if the data are placed accordingly;
- may result in a better utilization of each core's cache, because it would be reserved to a single swthread's data;
- may worsen the performance of synchronization constructs.
- may dispel the cache advantage if the swthreads are reading the same data

Symmetrically, having the swthreads "close" to each other:

- may decrease the latency of synchronization constructs;
- may decrease the aggregated bandwidth;
- may worsen/enhance the cache performance depending on what operations are performed on the data.

Threads affinity

OpenMP offers 2 basic concepts to set and control the affinity:

PLACES

i.e. to what physical entities (hwthread) we are referring to with our affinity request: "where" the threads run.

i.e. whether there is some relationship between threads and PLACES (in other words: between swthreads and hwthreads), and what relation is it.

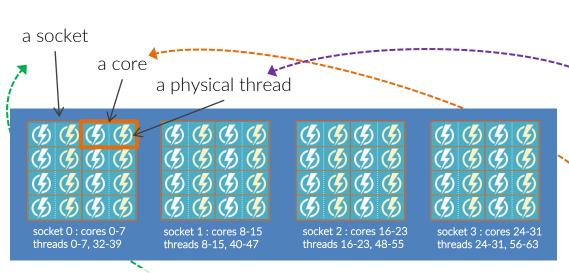

Threads affinity - PLACES

A typical example of configuration for a multicore, multisocket node: 4 sockets, each with 8 cores, each with 2 hwthreads.

Physical threads are exposed as "cores", numbered in a round robin fashion.

PLACES are where swthreads run.

The names for PLACES are:

- **THREADS** each place corresponds to a hwthread, or strand, on cores
- **CORES** each place corresponds to a single core (which may have more strands) on sockets
- **SOCKETS** each place corresponds to a physical sockets, with its multiple cores

NUMA node2 CPU(s):
                        24-35,72-83
```

36-47,84-95

The following examples will refer to a node like the one reported here on the left:

4 sockets 12 cores / socket 2 hwthreads / core

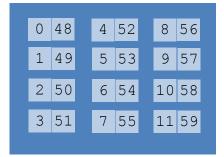

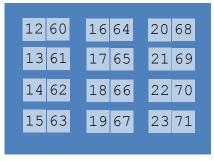

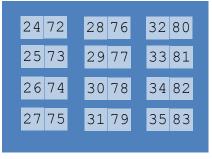

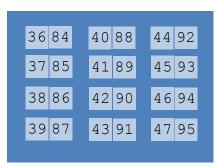

Socket 0 Socket 1 Socket 2 Socket 3

On a node the computational resources are identified as the physical threads numbered in a round-robin way.

If there are n_{sockets} with $n_{\text{cores-per-socket}}$ then there are

$$n_{\text{cores}} = n_{\text{sockets}} \times n_{\text{cores-per-socket}}$$
 $n_{\text{threads}} = n_{\text{cores}} \times n_{\text{SMT-threads}}$

The $n_{\rm threads}$ are the computational resources available on the node; in the following examples we do refer to these IDs

To clarify the numbering: if the same system shown in the previous slide had $n_{\text{SMT-threads}} = 4$ instead of 2 the numbering would have been as in the right instead of as in the left, here below.

SMT 2

NUMA node0 CPU(s): 0-11, 48-59

NUMA node1 CPU(s): 12-23, 60-71

NUMA node2 CPU(s): 24-35, 72-83

NUMA node3 CPU(s): 36-47, 84-95

NUMA node0 CPU(s): 0-11, 48-59, 96-107, 144-155

SMT 4

NUMA nodel CPU(s): 12-23, 60-71, 108-119, 156-167

NUMA node2 CPU(s): 24-35, 72-83, 120-131, 168-179

NUMA node3 CPU(s): 36-47, 84-95, 132-143, 180-191

Threads affinity - places

HOW TO PASS TO OPENMP YOUR PLACES DEFINITION:

the easiest and most practical way is through the env. variable **OMP_PLACES**

```
:> export OMP_PLACES = { sockets | cores | threads }
```

The names listed in the brackets refer exactly to what they mean:

threads : refer to logical cores i.e. it takes into account the SMT threads

cores : refers to physical cores

sockets : refers to sockets

However, we can be much more detailed if needed, as described in the following slides

{ 0, 48 }

{ 0, 12, 24, 36 }

Threads affinity - PLACES

A "place" can be defined by an unordered set of comma-separated non-negative numbers enclosed in braces (the numbers are the IDs of the smallest unit of execution on that hardware, a hwthread).

"unordered" means that the OS and OpenMP are free to use all the resources specified in the set without any specific priority.

{ 0, 1 }	this defines a place made by hwt 0 and hwt 1
	in the frame of the previous examples, these are the hwt on core 0 and core 1
	of socket 0

- this defines a place made by hwt 0 and hwt 48 in the frame of the previous examples, these are the hwt and the SMT hwt on core 0 of socket 0
- this defines a place made by hwt 0, 12, 24, 36 in the frame of the previous examples, these are the hwt on cores 0 of sockets 0, 1, 2 and 3
- { 0,1 }, { 1,49 } A list with two places

Threads affinitu

OMP PLACES can be defined as an explicit ordered list of comma-separated places (see the previous slide for a definition of "places").

Intervals can also be used, specified as start:counter:stride which results in the serie

```
start, start+stride, start + 2×stride, ..., start + (counter-1)×stride
```

sets OMP PLACES to 2 places OMP PLACES = in the frame of the previous examples, these are the hwt and SMT hwt on cores 0 and 1, { 0, 48}, {1, 49} respectively, of socket 0 OMP PLACES = the same than previous line { 0:2:48}, {1:2:48} OMP PLACES = SET OMP PLACES to 1 place $\{0, 12, 24, 36\}$ in the frame of the previous examples, these are the hwt on cores 0 of sockets 0, 1, 2 and 3 OMP PLACES = the same than previous line 0:4:12 }

`hreads affinit

Other examples of places definition by intervals:

```
{ 0 }:4:12
                                     \rightarrow { 0 }, { 12 }, { 24 }, { 36 }
{ 0:4:1 }:4:12
                                     \rightarrow { 0,1,2,3 }, { 12,13,14,15 }, { 24,25,26,27 }, { 36,37,38,39 }
{ 0:4}:4:4
                                     \rightarrow { 0,1,2,3 }, { 4,5,6,7 }, { 8,9,10,11 }, { 12,13,14,15 }
{ 0:4 }, { 4:4 }, { 8:4 }, { 12:4 }
                                     → Equivalent to OMP PLACES=sockets on a system with 4 sockets with 12 cores
{ 0:12 }:4:12
                                         each
```

The ! Operator can be used to exclude intervals.

The places are *static*: there is no way to change it while the program is running. It some of the specified places is not available, the behaviour is implementation dependent.

Threads affinity - places

HOW TO PASS TO OPENMP YOUR PLACES DEFINITION:

through the env. variable **OMP_PLACES**

```
:> export OMP_PLACES = { sockets | cores | threads }
```

```
:> export OMP_PLACES = "{0}:4:12"
```

Threads affinity - places

Resumé:

We have just learnt how to define the **places** the swthreads will run during execution.

Each place is composed by 1 or more physical resources that are pretty equivalent from the point of view of the OS or OpenMP (i.e. all the resources in a place are equivalently good/"legal" for the placement of a swthread).

The next fundamental question is how the swthreads are placed among the available places?

That is decided upon the **threads affinity policy**, which is defined through the "thread binding" on places: once the destination place for running has been decided, the swthreads are not allowed to move out of that place (it may be rescheduled on a different resource in the same place, but still in the same place)

The **BINDING** defines how the swthreads are mapped onto the PLACES.

The names for BINDING are listed here on the right

- **NONE** the placement is up to the OS
- CLOSE the swthreads are placed onto places as close as possible to each other (assigned to consecutive places in a roundrobin way)
- SPREAD the swthreads are placed onto places as evenly as possible, then the places are filled in a round-robin fashion
- MASTER the swthreads run onto the same place than master thread

HOW TO PASS TO OPENMP YOUR BINDING REQUEST:

(1) through the env. tariable OMP_PROC_BIND

:> export OMP_PROC_BIND = { false | true | master | close | spread }

this amounts to ask no policy (i.e. "none"), so that the O.S. will decide the placement, and to allow the O.S. to migrate the threads.

this amounts to ask no policy (i.e. "none"), so that the O.S. will decide the placement, BUT forbid the O.S. to migrate the threads.

these 3 options amount to ask a precise policsy and forbid the O.S. to migrate the threads.

(2) The binding can be specified in a non-persistent way for each parallel region *inside* the code:

```
#pragma omp parallel proc_bind(policy)
```

Once a swthread has been assigned to a hwthread, it is not allowed to migrate. If you have *nested parallelism*, you may define different behaviour for the nested regions

```
#pragma omp parallel proc_bind(spread)
{
    #pragma omp parallel for proc_bind(close)
    for ( int ii = 0; ii < local_N; ii++ )
}</pre>
```

• T ≤ P: there are sufficient places for a unique assignment. swthreads are assigned to consecutive places by their thread ID. The first place is the master's place. "consecutive" must be intended in physical sense, so that if the places is "threads" the hwthreads on a same core are the closest to each other.

CLOSE

• T > P: at least one place executes more than one swthread. swthread are splitted in P subsets St_i , so that

$$floor(T/P) \le St_i \le ceiling(T/P)$$

 St_0 includes swt 0 and is assigned to the master's place.

• $T \leq P$: place list is splitted in T subpartitions; each subpartition contains at least floor (P/T) and at most ceiling (P/T) consecutive places. A thread is then assigned to a subpartition, starting from the master thread. Then, assignment proceeds by thread ID, and the threads are placed in the first place of the next subpartition.

SPREAD

• T > P : place list is splitted in P subpartitions, each of which contains only 1 place and st, threads with consecutive IDs. The number of threads st; in each subpartition is chosen so that: $floor(T/P) \leq St_i \leq ceiling(T/P)$ At least one place has more than one thread assigned to it. The first subset with sto contains thread o and runs on the place that hosts the master thread.

places	THREADS	CORES	SOCKETS	Using the abs t names for place
CLOSE	swt are placed on close hwt, saturating all the SMT hwt in each core before using new cores	swt are placed on close hwt, using 1 hwt/core before starting to use SMT	swt are placed round- robin per socket, 1/core; after saturation, SMT is used by round-robin +1 hwt/socket	
SPREAD	swt are placed round- robin sockets, onto free cores in sockets	similar to ← SMT is avoided until saturation	similar to ← swt are placed by round- robin sockets and hwt	
MASTER	all swt are placed on the same hwt on the same core on the same socket	all swt are placed on the same core on the same socket, using all its hwt	all swt are placed on the same socket, saturing all hwt starting from SMT ones	note: swt = software hwt = hardware

```

Threads affinity – omp functions

The OpenMP standard offers several omp library functions to deal with the affinity.

You can study heir usage in the source files that are in the day17/examples/ folder

Setting the affinity proc bind clause Get the affinity omp get proc bind() Get details on places omp get num places () omp get place num() omp get place num procs() omp get place proc ids() Display affinity omp display affinity()

omp get affinity format (...)

omp set affinity format (...)

omp capture affinity (...)

Memory allocation

It is possible to control on what physical memory your data will reside by:

- 1. By carefully touching data
- 2. By changing default memory allocation with numact1
- 3. By explicit memory migration

We're **not** gonna cover this

| Memory allocation

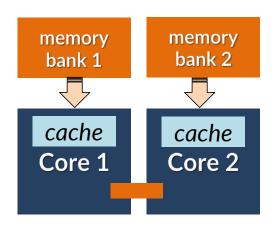

1. Careful data touching

Suppose that you are operating on a SMP system similar to the one depicted here on the left.

Each socket is physically connected to a RAM bank, and then physically connected to other socket. This way, the memory access is not uniform: the bandwidth for a core to access a memory bank not physically connected to it is likely to be significantly smaller than that to access the closest bank.

The matter is: who "owns" the data?

```
memory
                                                                       memory
double *a = (double*)calloc( N, sizeof(double);
                                                                        bank 2
                                                          bank 1
for ( int i = 0; ii < N; ii++ ) {
  a[i] = initialize(i);
                                                          cache
                                                                        cache
                                                         Core 1
                                                                       Core 2
#pragma omp parallel for reduction(+: sum)
for ( int i = 0; i < N; i++ )
     sum += a[i];
```

In this way, all the data are physically paged in the memory bank of the core on which the master thread runs; its cache is also warmed-up; the other thread must access the memory bank1 which is not the most suited for the bandwidth

parallel_loops/ 01_array_sum.c

The matter is: who "owns" the data?

```
double *a = (double*)calloc( N, sizeof(double);

for ( int i = 0; ii < N; ii++ ) {
    a[i] = initialize(i);

#pragma omp parallel for reduction(+: sum)
for ( int i = 0; i < N; i++ )
    sum += a[i];</pre>

memory bank 1

cache
Core 1

Core 2
```

In this way, the cache of the thread that initialize (first touch) the data is warmed-up and the data are allocated in the memory connected to it.

In the "touch-first" policy, the data pages are allocated in the physical memory that is the closest to the physical core which is running the thread that access the data first. If a single thread is initializing all the data, then all the data will reside in its memory and the number of remote accesses will be maximized.

The matter is: who "owns" the data?

```
why did I change from calloc to malloc?
parallel loops/
06_touch_by_all.c
                                                                                     _____ a[]
          double *a = (double*)malloc(N*sizeof(double));
                                                                                      memory
                                                                       memory
                                                                                      bank 2
                                                                        bank 1
         #pragma omp parallel for
          for ( int i = 0; ii < N; ii++ ) {
            a[i] = initialize(i);
                                                                       cache
                                                                                      cache
                                                                       Core 1
                                                                                     Core 2
         #pragma omp parallel for reduction(+: sum)
          for ( int i = 0; i < N; i++ )
                sum += a[i];
```

In this way, the cache of each thread is warmed-up with the data it will use afterwards and the data are allocated into each thread's memory (the scheduling must be the same!)

The matter is: who "owns" the data?

```
parallel_loops/
06_touch_by_all.c
```

why did I change from calloc to malloc?

```
ППП a[]
double *a = (double*)malloc(N*sizeof(double));
                                                          memory
                                                                        memory
                                                           bank 1
                                                                         bank 2
#pragma omp parallel for
for ( int i = 0; ii < N; ii++ ) {
  a[i] = initialize(i);
                                                          cache
                                                                        cache
                                                                        Core 2
                                                          Core 1
#pragma omp parallel for reduction(+: sum)
for ( int i = 0; i < N; i++ )
     sum += a[i]:
```

In this way, the cache of each thread is warmed-up with the data it will use afterwards and the data are allocated into each thread's memory (the scheduling must be the same!)

The difference between malloc and calloc

malloc

Notifies that the required amount of memory will be used, and the memory occupancy of the process in the heap is grown accordingly.

However, the actual mapping of the memory pages into the physical memory does *not* happen until the pages are actually "touched" (i.e. read or written).

Moreover, the mapping is done only for the touched pages, not for the entire amount of memory.

calloc

As for malloc, but with two fundamental differences:

- (1) the memory is required to be *physically contigous* (that is what the starting "c" means), and hence entirely on the same physical location;
- (2) all the memory is initialized to zero as a way to immediately "touch" it so that it is mapped onto a physical bank as soon as it is required.

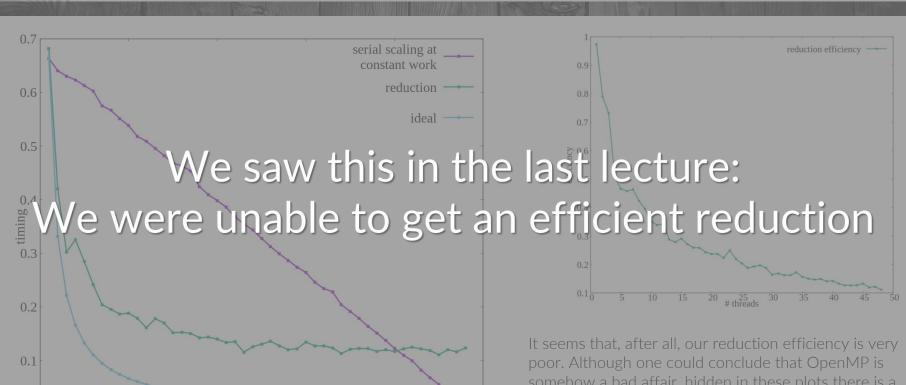

If each thread "touches" as first the data it will operate on subsequently, those data - by the "touch-first" policy - are allocated in the physical memory that is the closest. Hence, each thread will have its data placed in the most convenient memory and the remote accesses will be minimized

Solving the reduction / 6

40

threads

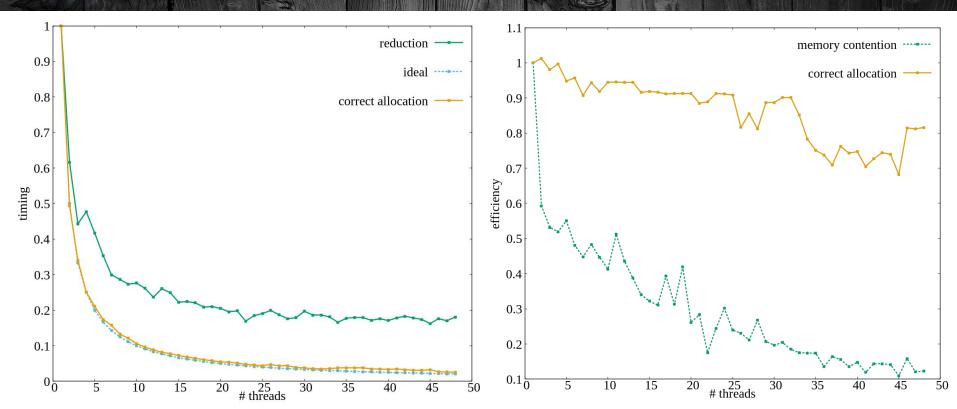

very important issue in multi-threading that we

inquire in the next lectures.

Discover your topology

Lots of tools are usually available on HPC platforms.

We'll see the details in the last lectures devoted to special topics

numactl --hardware a summary of the topology

this may change your general policy for membinding

lscpu

1stopo lstopo -s a summary of the topology

lstopo -v more verbose details

lstopo --only [core, socket, cache, pu, ..]

check the man page.. :)

hwloc hwloc-info, hwloc-distances, hwloc-ps, hwloc-ls, ...

likwid likwid-topology [-g]

likwid-pin <- this lets you pin your threads

/proc/cpuinfo

/sys/devices/system/

How to pin from command line

At least two handy tools:

taskset	-a pid	set/retrieve the CPU affinity for all the threads of a given PID $$				
	-c <mask></mask>	(hexadecimal) mask for cores (both physical and logical) 0×00000001 is cpu $\#0$ is cpu $\#0$, $\#4$ and $\#5$				
	cpu-list <list></list>	List of cores, may contain ranges 0-4,15-19 is cpu #0 to #4 and #15 to #19 0-12:2 is cpu #0, #2, #4, the :2 is the stride				
numactl	cpunodebind n	binds the execution to the NUMA nodes n (multiple nodes may be specified, see the man page)				
	membind <i>n</i>	binds the memory allocation to DRAM associated to NUMA nodes n (multiple nodes may be specified, see the man page)				

that's all, have fun
